#### **ABSTRACT**

Many banks provide supply-chain finance solutions that might include insurance services that further mitigate trade risk such as the default of suppliers. This study proposes the development of an insurance model that uses the Black-Scholes-Merton Model (BSM) (1973) for default prediction and risk pooling management techniques as a way to reduce the risk due to supplier bankruptcy and estimate an insurance premium that banks can use to charge this service to their customers. In order to demonstrate the use of the proposed insurance model, a sample of companies is selected from the New York Stock exchange and data for historical stock prices from the CRSP database (Center for Research in Security Prices) is collected in order to calculate the probability of bankruptcy of a sample of suppliers from different industries by using the BSM model. Twelve pools of companies of different sizes are created and a VBA program for Excel is developed in order to calculate probability of bankruptcy tables of companies belonging to the different pools. A Monte Carlo simulation to simulate the impact on risk and expected losses on the number of insurance policies sold is implemented with the use of simulation software. The results show that the simulation is useful to estimate the number of sold policies required in order to reduce the risk to a minimum level and predict with a high level of certainty the losses due to bankruptcy of suppliers. The expected losses for a risk pool can be used by a financial institution in order to price an insurance contract that hedges a company against the risk of default of suppliers.

#### **DECLARATION**

I hereby certify that this dissertation constitutes my own product, that where the language of others is set forth, quotation marks so indicate, and that appropriate credit is given where I have used the language, ideas, expressions, or writings of another.

I declare that the dissertation describes original work that has not previously been presented for the award of any other degree of any institution.

Signed,

Raul Valverde

#### ACKNOWLEDGEMENTS

To my Dissertation Advisor, Dr. Vasco Vendrame, who helped me with the focus of the dissertation, gave patient guidance throughout the full period and added helpful ideas.

I thank all my colleagues at Concordia University, who gave useful tips and a lot of assurance that I make it to "the end". To my family and friends, as their steady motivation pushed me through the final stage and never lost confidence (even when I did).

# Chapter 1. Introduction

Many banks provide supply-chain finance solutions that might include insurance services that further mitigate trade risk (see figure 1). A supply chain financial management insurance is a possible way to hedge a company against the risk of bankruptcy of suppliers. Although there is a need to offer suppliers default insurance as it is currently offered by institutions such as Zurich Insurance (Manmohan 2012), there is still little attention from academia for the development of an insurance model that can be used by institutions to offer this instrument that can protect against supplier's bankruptcy risk. This study proposes the development of an insurance model with the help of bankruptcy models and risk pooling management techniques. The model makes use of pooling arrangements and the Black-Scholes-Merton (1973), herewith referred to as BSM, bankruptcy model as a way to reduce the risk due to suppliers' bankruptcy and estimate an insurance premium that banks can charge to their customers for this service.

**Figure 1 Supply Chain Financial Services** 

#### 1.1 Approach

This study proposes the development of an insurance model with the help of bankruptcy models and risk pooling management techniques. The proposed model uses pooling arrangements and the BSM bankruptcy model as a way to reduce the risk due to suppliers' bankruptcy and estimate an insurance premium that banks can charge to their customers for this service. First, a sample of companies are selected from the New York Stock exchange and data for historical stock prices from the CRSP database (Center for Research in Security Prices) are collected in order to calculate the probability of bankruptcy of a sample of suppliers from different industries by using the BSM model. The data collected for this research is collected by using a judgment sampling method. A VBA program for Excel is developed in order to calculate the probability of bankruptcy with the help of the BSM model for the sample of selected companies. Risk pools are then created from the sample of companies and Monte Carlo simulations is conducted in order to estimate expected losses and risk.

#### The research questions are:

- i) Can the propose supply chain risk management insurance model reduce the risk of bankruptcy of suppliers in a corporate setting?
- ii) Is the model appropriate to calculate an insurance premium that could be used to implement the insurance model by insurance and financial institutions?

## Chapter 2. BACKGROUND AND REVIEW OF LITERATURE

#### 2.1 Background

In this chapter, a review of supply chain finance literature is conducted in order to understand better the application of finance and accounting concepts in the offering of financial services for supply chain such as insurance services. Risk management for Supply Chain will help to understand the critical risk management issues that affect supply chains. The discussion of the Credit Analysis literature will help to understand the different techniques used by banks to estimate default probabilities of institutions that can help us to feed risk management models that can be used to offer insurance services for the supply chain. Risk pooling literature will help to understand how this concept can be used to develop insurance services in the supply chain services industry. Finally, literature on Monte Carlo analysis will help us to understand how this technique can be used to validate the model and estimate losses that can be used to valuate insurance premiums, estimate maximum losses and risk estimates. The literature is divided in multiple themes including Supply Chain Finance, Risk Management in Supply Chain and Credit Risk Management.

#### 2.2 Supply Chain Finance

Companies are increasingly forming global supply chains and favouring global sourcing practices to lower the purchase prices (Valverde & Saade 2015)(Valverde 2012). Although supply chain management has been used in practice during several decades, a new trend of developing financial services for the supply chain has emerged in the last ten years (Popa 2013)(Khan & Valverde 2014); this has originated the concept of Supply Chain Finance (SCF). There are several definitions of SCF. According to Killen and Associates (2002), SCF represerved.

sents all transaction activities that go from the flow of cash from the customer's initial order through reconciliation and payment to the seller. Lamoureux and Evans (2011) define SCF as the sequence of financial events and processes that take place as commercial transactions are executed. Popa (2013) also recognizes that SCF is different from the physical supply chain as it deals with the flow of cash instead of goods (Popa 2013). SCF has been recognized as an important issue in the supply chain mainly because its bad management can cause late delivery, negative cash positions and poor working capital management. SCF deals with many aspects of the supply chain including Supplier Risk Management, Supply Chain Financing, Tax Optimization, working capital optimization (including inventory) and the Impact of purchasing and supply chain management on key financial performance ratios. SCF, in general, will translate into cost reduction, service improvement, better risk management and richer management information from a buyer and supplier perspective. SCF also requires collaboration of partners that are committed to sharing resources, capabilities, information and risks on a medium to long term contractual basis while preserving their legal and economic independence (Popa 2013).

Although the concept of supply chain finance is still expanding in scope, banks have initially understood SCF as a marketing umbrella to repackage traditional products such as trade, insurance, payments and cash management (Popa 2013). However, SCF now has been expanded to include working capital management and the offering of risk management services. Since many banks provide supply-chain finance solutions, this might include insurance services that further mitigate trade risk. A supply chain insurance can be a possible way to hedge a company against the risk of bankruptcy of suppliers. This event can generate losses and extra costs that include (a) losses due to supply chain disruption, (b) delayed or stopped finished goods shipments, (c) difficulty in finding

cost-effective alternate suppliers and sourcing contracts, (d) emergency procurements, (e) loss of reputation and market share loss, among others. In summary, If a supplier goes bankrupt, that firm may not be able to meet all of its customer requirements in the short-term, and will not meet any customer requirements if it eventually goes out of business (Zsidisin 2010).

In the next section, financial risk management in the SCM will be discussed.

#### 2.3 Risk Management in Supply Chain

Risk management is a critical part of supply chain management (SCM) as the risk of bottlenecks, disruptions and incurring unforeseen costs are greater in cross continent and global supply chains. Supply chains are surrounded by potential risks including natural disasters, fraud, economic issues, changes in tax laws, disruptions caused by suppliers' bankruptcy, interest rates and foreign exchange rates fluctuations among other things (Kraus & Valverde 2014). Supply Chain Risk Management (SCRM) includes strategies to manage risks along the supply chain (Shi 2004)(Stephens & Valverde 2013). The growing incidence of natural disasters caused by climate change, terrorist acts, embargoes, fraud, money laundering and economic volatility adds to the risk profile of a global supply chain.

Issues associated with risk and continuity in the supply chain have received considerable attention from both the practitioner and academic communities (Zsidisin 2010). Supply chain risks can generate losses that can be at times quite large due to the disruption of the supply chain. Losses can include loss of reputation, emergency procurement, delays in the production among others.

SCF has been used for the risk management of supply chains. SCF includes risk mitigation instruments such as trade credit insurance that protect suppliers

against the risk of non-payment by foreign buyers (Lamoureux 2011) (Valverde & Talla 2013). Supplier risks can also be reduced by financial risk management strategies such as attenuating price volatility of supplier pricing for goods and services through negotiation of long term contracts and consolidation of requirements with other firms/organizations, minimization of currency risk on contracts denominated in foreign currencies through the various forms of hedging (e.g. forward contracts, futures contracts), minimizing the risk of potential supplier bank-ruptcy through financial analysis and surveillance and minimizing the cost of supplier financing in developing and emerging markets by providing advanced payments (Lamoureux 2011). A firm is obliged to evaluate the financial viability of suppliers in order to avoid the consequences of suppliers' default, insolvency, or bankruptcy (Milne, 2010; Wagner et al, 2004).

Consulting firms such as Deloitte and PriceWaterhouseCoopers (PWC) and insurance companies such as Zurich Insurance provide consulting services on assessing and mitigating supply chain risks arising from product development to outsourcing and from finance to logistics (Manmohan 2012). Zurich's supply chain risk management practice provides consulting services to reduce supply chain failures and insurance coverage including supplier defaults and supply delay so that the insurer can reduce financial risk exposure (Manmohan 2012).

In the next section, Credit Risk Management techniques will be discussed to understand the different mechanisms that a bank can use in order to determine default probabilities that can be used in the development of insurance services.

#### 2.4 <u>Credit Risk Management</u>

Credit risk arises from the possibility that borrowers, bond issuers, and counterparties in derivatives transactions may default (Hull 2012) (Valverde 2011). Typically it is measured by credit ratings, but most banks have their own internal ratings systems for borrowers. There are several techniques for Credit-risk analysis including credit ratings and mathematical models such as the Z-Score (Altman 2000) and Black-Scholes-Merton (BSM) model (Black & Scholes1973).

#### 2.4.1 Credit Ratings

One of the rating agencies' objectives is ratings stability. Rating agencies want to avoid ratings reversals whereby a firm is downgraded and then upgraded a few weeks later. Ratings therefore change only when there is reason to believe that a long-term change in the firm's creditworthiness has taken place. The reason for this is that bond traders are the major users of ratings. Often they are subject to rules governing what the credit ratings of the bonds they hold must be. If these ratings changed frequently they might have to do a large amount of trading just to satisfy the rules. Rating agencies try to 'rate through the cycle'. Suppose that an economic downturn increases the probability of a firm defaulting in the next 6 months, but makes very little difference to the firm's cumulative probability of defaulting over the next three to five years. A rating agency would not change the firm's rating (Hull 2012).

Most banks have internal credit ratings that assess the creditworthiness of their corporate and retail clients. The internal ratings based (IRB) approach in Basel II allows bank to use their internal ratings in determining the probability of default, PD. Under the advanced IRB approach, they are also allowed to estimate the loss given default, LGD, the exposure at default, EAD, and the maturity, M (Hull 2012).

#### 2.4.2 Altman's Z-score

The Altman's Z-score uses a discriminant analysis that attempts to predict defaults from five accounting ratios.

$$Z-Score = 1.2A + 1.4B + 3.3C + 0.6D + 1.0E$$
 (1)

where:

A = Working Capital/Total Assets

B = Retained Earnings/Total Assets

C = Earnings Before Interest & Tax/Total Assets

D = Market Value of Equity/Total Liabilities

E = Sales/Total Assets

All variables are scaled by total assets, except for market value of equity, which is scaled by book value of total liabilities. If Z-score > 3, the firm is unlikely to default. If it is between 2.7 and 3.0, we should be 'on alert'. If it is between 1.8 and 2.7, there is a good chance of default. If it is less than 1.8, then the probability of a financial embarrassment is very high (Altman 2000).

A paper published by (Grice & Ingram, 2001), explored the generalizability of Altman's Z-score model in modern times. The authors claim that the model is designed for old style parameters and firm characteristics, so it is not so useful for bankruptcy prediction of contemporary firms, but it can be still useful for predicting financial stress conditions. The authors also argue that the model does not account for non-financial events, this is a limitation of the model as it does not capture all events that may cause bankruptcy (Grice & Ingram, 2001).

#### 2.4.3 Black-Sholes-Merton model

A model that is used to ensure that an instrument is priced consistently with the observed market prices of other similar instruments is the Black-Scholes-Merton model (BSM) (Hull 2012). The BSM option pricing model (Black & Scholes1973) can be used to estimate the probability of bankruptcy of suppliers by extracting and examining the riskiness in the stock market price of suppliers. The model assumes: maturity of liabilities equals one year; the dividend rate is based on the sum of common dividends, preferred dividends, and interest expense; call option equation has been modified to account for the fact that shareholders receive common dividends (Black & Scholes1973). Merton (1974) mathematically developed the options pricing model for the valuation of derivatives that lead to the generation of new types of financial instruments and facilitated more efficient risk management in society,

The basic idea for estimating the probability of a supplier company bankruptcy is to recognize the stock price movement pattern of the supplier company, and evaluate historic events information, which is available to the public via company press meets, market focus, and so on. The procedure for extracting such information was developed by Hillegeist et al (2004).

According to option-pricing theories (Black & Scholes1973), a market-based measure, that is called Black-Sholes-Model probability of bankruptcy (BSM-PB), should use all available information about the probability of bankruptcy. The BSM-PB contains relatively more information than just the Score variables used traditionally for bankruptcy prediction; however the accounting measures will not be incrementally informative to BSM-PB. Hillegeist et al (2004) tested the validity of these implications using a large sample consisting of 65,960 firm-year observations including 516 bankruptcies during the period 1979-1997. They found that

BSM-PB has relatively more explanatory power than either of the two scores, even when the scores are decomposed to reflect industry differences or annual changes.

The model assumes that volatility is a crucial variable in bankruptcy prediction since it captures the likelihood that the value of a firm's assets will decline to such an extent that the firm will be unable to repay its debts. Equity can be viewed as a call option on the value of the firm's assets. The strike price of the call option is equal to the face value of the firm's liabilities and the option expires at time T when the debt matures.

.

#### 2.4.4 Comparison between different credit analysis methods

Although the Z-Score model seems to be quite simple to calculate and interpret, Hillegeist et al (2004) recommends the use of the BSM for default probability calculations mainly because it provides relatively more information than just the score variables used traditionally for bankruptcy prediction with Z-Score model. However, the main weakness of the BSM is that it relies on stock market information that might not be available for all the companies (in the particular case of this research, this means the suppliers that are part of a supply chain). The other weakness is its complexity; the calculation of BSM requires a strong finance theory background that might not be part of the profile of a typical supply chain manager. Also, the accounting measures will not be incrementally informative to BSM model as it is with the Z-Score model.

On the other hand, Z-Score values can be calculated for any company that is willing to disclose financial statements even if these are not public. However, the Z-Score value is not a probability itself but just a score value that can determine

the likelihood that a company will go bankrupt but it does not generate a probability number and therefore cannot be used to prepare a probability distribution used for insurance purposes.

Credit ratings used by banks are mainly classification systems that can help a bank manager to easily determine the interest rates of a loan without complex calculations. However, they do not allow to determine probabilities that can be used to determine probability distributions required to implement insurance services.

From the three options reviewed, the BSM is the model that best serves the purpose to implement insurance services models. The next section examines the concept of risk pooling in insurance services.

## 2.4.5 Risk Pooling for Risk Management

A risk pool is one of the forms of risk management practiced in insurance. Pooling arrangements do not change a company's expected loss, but reduce the uncertainty (standard deviation) of a loss. Risk pooling arrangements make each participant's loss more predictable (McDonald et al. 2006). A risk pool is one of the forms of risk management practiced in insurance.

Correlation analysis is very important in pooling arrangements. A positive correlation in losses is less desirable than null correlation (uncorrelated losses) in the context of risk management. While a positive correlation in losses reduces the extent to which risk pooling lowers the standard deviation of losses, null correlation in losses increase it.

The concept of pooling losses has been used in supply chain (Levi et al. 2003) for inventory management. Risk pooling suggests that demand variability is reduced

if demand is aggregated across locations because as demand is aggregated across different locations, it becomes more likely that low demand from one customer will be offset by high demand from another. This reduction in variability leads to a decrease in safety stock and therefore reduces average inventory. This suggests that the use of centralized warehouses would be able to reduce inventory costs as it reduces safety stock but this benefit will decrease as the correlation between demand of two different locations demanding inventory becomes positive (Levi et al. 2003).

In general, risk pooling has a number of advantages when it comes to risk management. Losses become more predictable, the maximum probable loss declines, and the distribution of costs becomes more symmetric. The predictability increases with the number of participants and decreases with correlation in losses.

In the case of insurance, this means that the more insurance policies are sold by a bank or insurance company the more predictable the expected losses will be and the lower the probability of extreme losses will be. However, insurance companies and banks should be aware that losses events should have low correlation for the pooling arrangements to work this way. Risk pooling can be used to generate the probability distributions that in combination with other mathematical methods such as Monte Carlo analysis can be used to simulate scenarios for different number of insurance contracts and estimate risk and average losses. Monte Carlo analysis is covered in more detail in the next section.

#### 2.4.6 Losses estimation via Monte carlo analysis

Monte Carlo analysis is a technique that is used in Finance in order to simulate losses in financial risk management (Hull 2012). The idea of Monte Carlo simula-

tions is to generate random numbers in order to model the stochastic behavior of an input parameter. Each different sequence of random numbers causes another result.

Given a probability distribution of losses, Monte Carlo analysis can be used to estimate the average, total and variance of the losses after a determined number of events. The analysis can be quite useful to estimate premiums and risk for insurance services (Korn et al 2010). In the case of insurance, Monte Carlo analysis can be used to estimate the total, variance and average losses given a number of policies sold. Monte Carlo analysis only requires a probability or frequency distribution that can be sampled from historical data or calculated based on mathematical models such as the BSM Model.

Monte Carlo simulations have a successful history of providing reliable results for supply chain risk management and finance. Deleris et al (2004) uses Monte Carlo simulations to estimate the probability distribution of supply chain losses caused by disruptions. Cohen and Huchzermeier (1999) use Monte Carlo simulations to produce accurate estimates of the firm's downside risk exposure to price/foreign exchange rate risk in the supply chain. Grittner and Valverde (2012) use Monte Carlo simulations for the estimation of reordering points in the embedded systems industry by using historical demand taken from an Enterprise Resource Planning system. Stafanovic et al. (2008) use Monte Carlo simulation to generate demand as an external event to a system modeling in a supply network; the authors are able to demonstrate that Monte Carlo can be used to simulate supply chain risk events and are also able to show that Monte Carlo can be used as part of a simulation framework that can be used by supply chain professionals. Qin and Ding (2011) simulate the operations of the supply chain, interactions with a bank and the bank behaviour for inventory financing model for supply chain risk management.

Given the amount of random variables in the supply chain financial risk management field, Monte Carlo analysis is a justifiable research tool as it is capable of handling situations with a certain degree of uncertainty as long as the behaviour can be modeled with a probability distribution.

#### 2.5 Summary

From this literature review several lessons and concepts can be learned. First, the extant literature supports an increasing use of financial theory in supply chain management. Several companies around the world are offering financial services for supply chain management including insurance services. This serves as a justification of this research as the proposed research intends to use financial risk management theory to solve a supply chain problem that is the losses caused by bankruptcy of suppliers.

In this chapter, risk management issues in supply chain management were reviewed including the risk of bankruptcy of suppliers that is the main focus of this study. Different credit analysis mechanisms were reviewed and the Black-Scholes-Merton model was justified for this study mainly because it fits the best the development of an insurance model that could be easily created with available public stock market data. Risk pooling in insurance was reviewed as the main tool to reduce risk by selling a large number of insurance contracts and by helping in the estimation of insurance premiums. Monte Carlo analysis principles were reviewed and justified as a good option for this research given that the existent literature provides evidence of good results in finance and supply chain management research.

In general, this literature review helped to identify the need for an insurance model for supply chain management that, for this study, is concentrated mainly on the risk of bankruptcy of suppliers but that can be extended in the future to other types of risks. The literature review also provided the necessary theoretical background to perform this study.

# Chapter 3. RESEARCH METHODOLOGY AND RESEARCH DESIGN

This chapter outlines the research methodology and design for this study. It starts with the research questions and also covers the data collection techniques, mathematical models used, simulation techniques and the limitations for this research.

#### 3.1 Research questions

The research questions of this research are:

- i) Can the proposed supply chain risk management insurance model reduce the risk of bankruptcy of suppliers in a corporate setting?
- ii) Is the proposed model appropriate to calculate an insurance premium and risk that can be used by insurance and financial institutions to implement the insurance model?

#### 3.2 <u>Data collection</u>

The research will use the Black-Scholes-Merton (BSM) option pricing model for estimating the probability of bankruptcy of suppliers based on the financial data collected for historical stock prices from the CRSP database (Center for Research in Security Prices).

The data collected for this research will be collected by using a judgment sampling method. Remenyi et al (1998) acknowledge that judgment samples are inherently subjective but justify the use of judgment samples on the grounds that "samples are taken where individuals are selected with a specific purpose in mind, such as their likelihood of representing best practice in a particular issue". From the outset it became clear that statistical sampling techniques on this type of research would have not been possible given the large amount of companies that act as suppliers for companies, this would have resulted an extremely high sample size that could not be computed for this dissertation given time limitations. The proposed sample size is 100 companies from a variety of industries operating in four different sectors: Energy, Consumer Durables, Technology, and Capital goods. These industries were judged appropriate for the study given their large number of suppliers and potential of losses due to supplier bankruptcy. This sample, in the opinion of the author, should be large enough to test the proposed model.

Data collected for the purpose of this analysis was obtained from two resources. First, listings were collected from NASDAQ's website (http://www.nasdaq.com/screening/companies-by-industry.aspx?) for organizations operating in four different sectors: Energy, Consumer Durables, Technology, and Capital goods (See figure 2). These industries were considered appropriate as organizations operating in these heavy or industrial goods industries will

likely incur excess costs should a supplier declare bankruptcy. Examples of industries excluded were public utilities, transportation, and finance, which represent service based organizations that are not the focus of this research. In all, 1,046 company names were extracted, from which a convenience sample of 100 organizations was extracted.

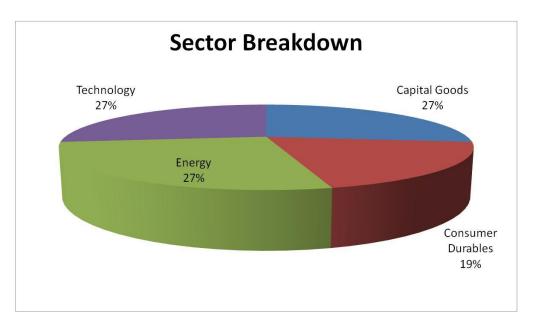

Figure 2 Sector Breakdown

The daily stock price data from January 1st 1994 to 2014 (the last twenty years) was then collected via the CHASS Data Centre (University of Toronto) CRSP Database, with the common assumption that the average number of Trading days in one year is 252.

#### 3.3 Treasury Bills Free rate

The risk free rates for the last 10 years were downloaded (Bank of Canada, http://www.bankofcanada.ca/rates/interest-rates/t-bill-yields/selected-treasury-bill-yields-10-year-lookup/) for T-bills with 1-month, 3-month, 6-month, and 1-year maturity. A 10-Year average yield of the different term Treasury Bills was calculated and documented in table 1.

**Table 1 Treasury Bills Free Rate** 

| 1-Month | 3-Month | 6-Month | 1-Year | Average |
|---------|---------|---------|--------|---------|
| 0.0178  | 0.0186  | 0.0197  | 0.0197 | 0.0193  |

#### 3.4 Black-Scholes Model

The BSM model is used to calculate the probability of bankruptcy for the sample of firms selected for this study.

The equation for valuing equity as a call option on the value of the firm's assets is given in equation 2 (Hull 2012). This equation is modified for dividends and reflects that the stream of dividends paid by the firm accrues to the equity holders.

The BSM equation is:

$$E_0 = V_0 N(d_1) - De^{-rT} N(d_2)$$
 (2)

Where  $N(d_1)$  and  $N(d_2)$  are the standard cumulative normal of  $d_1$  and  $d_2$  which are:

$$d_{1} = \frac{\ln(V_{0}/D) + (r + \sigma_{V}^{2}/2)T}{\sigma_{V}\sqrt{T}}; d_{2} = d_{1} - \sigma_{V}\sqrt{T}$$
(3)

 $E_0$  is the current market value of equity;  $V_0$  is the current market value of assets; D is the face value of debt maturing at time T; r is the continuously-compounded risk-free rate and  $\sigma_V$  is the standard deviation of asset returns.

Equation (4) (Hull 2012) together with the option pricing relationship described in equation 3 enables  $V_0$  and  $s_V$  to be determined from  $E_0$  and  $\sigma_E$ .

$$\sigma_E E_0 = \frac{\partial E}{\partial V} \sigma_V V_0 = N(d_1) \sigma_V V_0 \tag{4}$$

Under the BSM model, the probability of bankruptcy is simply the probability that the market value of assets,  $V_0$  is less than the face value of the liabilities, D, at time T (i.e  $V_0(T) < D$ ). The BSM model assumes that the natural log of future asset values is normally distributed. The probability of bankruptcy is a function of the distance between the current value of the firm's assets and the face value of its liabilities, adjusted for the expected growth in asset values relative to asset volatility.

As shown in (Black & Scholes1973), the probability that  $V_0$  (T) < D or probability of bankruptcy can be calculated as indicated in equation 5(Hull 2012):

$$N(-d2) (5)$$

An Excel spreadsheet is developed in order to calculate the probability of bank-ruptcy with the help of the BSM model for the sample of selected companies. The BSM model is fed by using daily return data from the Center for Research in Security Prices database (http://www.crsp.com).

The Excel spreadsheet with the help of the solver module is used to calculate the probability of bankruptcy. The calculation is performed in three steps. In this initial step,  $E_0$  will is set equal to the total market value of equity based on the closing

price at the end of the firm's fiscal year,  $\sigma_{\rm E}$  is computed by using daily return data from the historical stock prices from the Center for Research in Security Prices database (http://www.crsp.com) over twenty years of trading data. D is set equal to the book value of total liabilities, T is equal to one year, and r is set at the one-year treasury bill rate. In the second step, the values of  $d_1$ ,  $d_2$ ,  $\sigma_V$  and  $V_0$  are estimated by simultaneously solving equations 2, 3 and 4.

Finally, the value of  $d_2$  is used to calculate the probability of bankruptcy for each firm-year via equation 5 by using the standard normal distribution of - $d_2$ .

#### 3.5 Risk pooling

The research use pooling arrangements among suppliers as a way to reduce the risk due to supplier bankruptcy. The pooling arrangement can be used by an insurance company to reduce risk and estimate an average loss that can be used to estimate insurance premiums. A risk pool is one of the forms of risk management practiced in insurance. Pooling arrangements do not change a company's expected loss, but reduce the uncertainty (standard deviation) of a loss. Risk pooling arrangements make each participant's loss more predictable (McDonald 2006).

This study plans to use pooling arrangements among suppliers as a way to reduce the risk of suppliers' bankruptcy. Pooling arrangements of 5, 10, 25 and 50 companies with 3 different sets of companies are created in order to see the effect of the number of companies in terms of risk reduction and to estimate an average loss that can be used to estimate insurance premiums

The concept of pooling losses has been used in supply chain (Simchi-Levi, 2009). Risk pooling suggests that demand variability is reduced if one aggregates demand across locations because as demand is aggregated across different locations, it becomes more likely that high demand from one customer will be offset by low demand from another. This reduction in variability allows a decrease in safety stock and therefore reduces average inventory, this suggests that the use of centralized warehouses reduces inventory costs as it reduces safety stock but this benefit decreases as the correlation between demands of the different locations becomes positive (Simchi-Levi, 2009).

Once the probability of bankruptcy for the sample of 100 companies has been compiled, a loss distribution is computed in order to determine the probability of having 1, 2, 3, ... 100 companies going bankrupt on a given year. This helps us to determine the probability of number of insurance claims during a year.

For a given number of possible bankruptcy events, the probability of no events or no bankruptcies is defined in equation 6:

$$S = \{1, 2, 3, \dots, x\}$$
 for  $x > 1$ 

$$P(0) = \prod_{i=1}^{i=x} (1 - Pi) \tag{6}$$

The probability of a given number of bankruptcies to occur (n) for a given possible set of companies (x) is described in equation 7:

$$P(n) = P(0) \sum_{i1,i2,\dots,in \in S, ik \ distinct} \frac{Pi_1 Pi_2 Pi_3,\dots,P_n}{(1-P_1)(1-P_2)(1-P_3),\dots,(1-P_n)}$$
(7)

Where there are  $\binom{x}{n}$  terms in the summation.

For example, let us assume that we have 3 companies with a probability of bank-ruptcy for company 1 of 0.01, company 2 of 0.02 and company 3 of 0.015. The probabilities of 0, 1, 2 and 3 bankruptcies are calculated as follows:

$$S = \{1,2,3.\}$$
 for  $x = 3$ 

$$P(0) = (1 - .01)(1 - .02)(1 - .015) = 0.955647$$

$$P(1) = 0.955647 \times \left( \frac{0.01}{1 - 0.01} + \frac{0.02}{1 - 0.02} + \frac{0.015}{1 - 0.015} \right) = 0.043709$$

$$P(2) = 0.955647 \times \left( \frac{(0.01)(0.02)}{(1 - 0.01)(1 - .02)} + \frac{(0.02)(0.015)}{(1 - 0.02)(1 - 0.015)} + \frac{(0.01)(0.015)}{(1 - 0.01)x(1 - 0.015)} \right) = 0.000641$$

$$P(3) = 0.955647 \times \left( \frac{(0.01)(0.02)(0.015)}{(1 - 0.01)(1 - 0.02)(1 - 0.015)} \right) = 0.000003$$

#### 3.6 Monte Carlo simulations

In order to tackle the issues of validity and reliability, the study plans to validate the proposed model by simulating a possible bankruptcy of multiple suppliers based on the calculated probabilities and show that the model can be successful as a way to reduce the risk of supplier bankruptcy. The simulation also has the objective of showing that the average losses would be more predictable and used to calculate an insurance premium.

Monte Carlo simulations have a good history of providing reliable results for supply chain risk management. Deleris et al (2004) used Monte Carlo simulation to estimate the probability distribution of supply chain losses caused by disruptions, Cohen and Huchzermeier (1999) used Monte Carlo simulations in order to pro-

duce accurate estimates of a firm's downside risk exposure to price/foreign exchange risk in the supply chain.

A Monte Carlo simulation for the bankruptcy of companies for multiple periods with the probabilities calculated with the BSM model is performed in this research. The objective of the simulation is to calculate losses for the bankruptcy of suppliers and compare them with the premium calculations. The simulation helps to test whether the risk management model is able to reduce the variability of losses and whether the estimated insurance premium are able to cover for all the losses. Ten simulations are performed for each risk pool of 5, 10, 50 and 100 in order to verify the results. An estimated expected loss and variance for each risk pool are calculated.

#### 3.7 Limitations

The proposed study is limited to suppliers that are traded in the New York stock exchange market. This limits the results to only those companies that are traded in the financial market.

Given the time limitations and the large number of companies available, the research proposes a non probabilistic sampling method for simplicity. This makes generalization and inference about the entire population difficult.

#### 3.8 Summary

This chapter has outlined the research design and methodologies that will be used for this dissertation. First, a sample of 100 companies is used to collect data from the CRSP database that is used to calculate the probability of bankruptcy of suppliers. Risk pooling is then used to create an insurance instrument that can be

used to insure companies against supplier bankruptcy. A Monte Carlo simulation is used to calculate expected losses and risk for pools of companies of different sizes with the intention to show how this tool can be used to calculate expected losses and risk that can be useful to estimate insurance premiums.

## Chapter 4. **RESULTS AND DISCUSSION**

#### 4.1 Probability of bankruptcy

The probability of bankruptcy for the sample of 100 companies was calculated by using the BSM model and the Excel Solver. In the initial step,  $V_E$  was set equal to the total market value of equity based on the closing price at the end of the firm's fiscal year,  $\sigma_E$  was computed using daily return data from the Center for Research in Security Prices database (http://www.crsp.com) over the period of twenty years. T was equal to one year, and r was set as the one-year treasury bill rate calculated in Table 1. Moreover,  $E_0$  was set to the current market value of equity and D at the face value of debt maturing at time T. Appendix 1 shows these values that were used to feed the BSM model.

The values of  $d_1$ ,  $d_2$ ,  $\sigma_V$  and  $V_0$  were estimated by simultaneously solving equations 2, 3 and 4 with the use of an Excel spreadsheet and by using the solver module. The results of these calculations are documented in appendix 1. The value for  $d_2$  was used to calculate — the probability of bankruptcy for each firm-year via equation 5 by using the standard normal distribution of  $-d_2$ . The probability of bankruptcy generated for each company is presented in Table 2.

#### 4.2 Risk Pools

Pooling arrangements of different sizes (5, 10, 25 and 50 companies) for 3 different set of companies were created. Appendix B contains the tables of the different pooling arrangements with the different set of companies that are used in this study. For each pooling arrangement, a probability table was calculated by using equations 6 and 7 and with the help of a VBA program for Excel. The VBA program (Appendix D), reads the probabilities of bankruptcy for each company in each of the pooling arrangements and uses equations 6 and 7 to compute the probabilities that suppliers will go bankrupt in a year. For example, in Table 19, the probability that no company goes to bankrupt for sample 4 (10 companies) is 90%, the probability that only one company goes out of business is 9.6%. The same Table also shows that the probability that 5 or more companies go bank-

ruptcy is close to zero. It is interesting to notice that the probability of no bank-ruptcy is the highest for all tables. These probability tables for all the different pooling arrangements used for the study are included in Appendix C.

#### 4.3 Monte Carlo simulation

A Monte Carlo simulation was performed in order to calculate the expected losses of bankruptcy and standard deviations of losses for the different risk pooling arrangements for this study. POM for Windows Software (http://wps.prenhall.com/bp\_weiss\_software\_1/) was used for this simulation. POM is a management science software that supports Monte Carlo simulations. The tables with the risk pooling arrangements probabilities included in Appendix C were loaded into POM in order to perform the simulation. Figure 3 shows Table 24 in Appendix C, this table contains the probabilities of losses for a risk pooling arrangement of 10 companies for sample 6. The number of trials in the simulation represents the number of policies that can be sold by an insurance company, for each simulation the number of trials was set to 5, 10, 50 and 100.

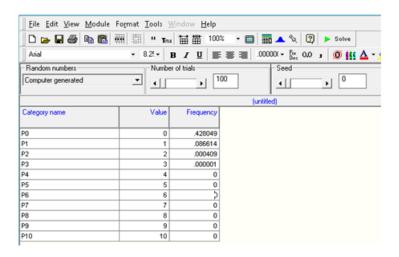

Figure 3 POM Simulation for 10 companies for Sample 6

For each risk pooling arrangement, 100 simulations were performed and average standard deviations computed and reported in Tables 3 and 4.

Table 3 Results for the simulation for samples 1, 2, 3, 4, 5 and 6 with Standard Deviation for various quantities of policies sold

| for various<br>quantities<br>of policies | 100 Policies<br>Standard Devia-<br>tion | 0.0534           | 0.0295   | 0.0459   | 0.3552           | 0.3619    | 0.0844    |
| sold                                     | % Change Stan-<br>dard Deviation        | -82%             | -82%     | -81%     | -69%             | -57%      | -67%      |

Tables 3 and 4 confirm that standard deviations (measurement of risk) are reduced by increasing the number of insurance policies being sold. The standard deviations are being reduced to a maximum of 84% by increasing the sale of insurance policies from 5 to 100 policies per risk pool arrangement. The simulation proves to be an excellent tool to measure risk with a given number of policies being sold.

Costs in the case of a partner organization declaring bankruptcy include administrative costs, related to the closure, shortages and stock outs, and loss of goodwill and reputation; all are possible side effects and are difficult to measure. In the case of industrial sectors like automotive and aerospace, substantial costs will be incurred in substantiating new suppliers and parts as decreed by the transportation regulatory body. The loss per bankruptcy for the simulation was simply set to a convenience value of \$50,000 to demonstrate that with the knowledge of the insurance per bankruptcy claim value, one could compute expected losses for the risk pooling arrangement or insurance payout (Pindyck and Rubinfeld 2005). The loss per bankruptcy represents the payout in the insurance contract that the insurance company needs to pay per bankruptcy.

The average expected losses represent the minimum value that must be collected to ensure that the insuring organization breaks even on a policy in which the payout per bankruptcy is \$50,000. Table 5 includes the average expected losses for the different samples included in this study for the 100 Monte Carlo simulations performed for this research.

Table 5 Average Expected losses for the simulation for the different samples

| # Companies | Sample<br># | olicy Average<br>pected Loss | 10 Policy Aver-<br>age Expected<br>Loss | Policy Aver-<br>Expected | 100 Policy<br>Average Ex-<br>pected Loss |

|             | 9           | \$<br>19,200.00              | \$ 18,850.00                            | \$<br>18,700.00          | \$ 18,880.00                             |
|             | 10          | \$<br>77,300.00              | \$ 85,150.00                            | \$<br>80,620.00          | \$ 80,915.00                             |
| 50          | 11          | \$<br>97,200.00              | \$ 94,200.00                            | \$<br>96,530.00          | \$ 95,890.00                             |
|             | 12          | \$<br>15,800.00              | \$ 14,950.00                            | \$<br>15,440.00          | \$ 14,565.00                             |

By examining Table 5, we can observe that expected losses become more predictable as we increase the number of policies sold. For example, for sample 5, there is a difference of only \$45 between 100 and 50 policies sold. This means that the insurance company could expect to lose around \$1,700 per insurance policy sold if the company is being able to sell at least 50 policies. The simulation can be used as a tool to estimate expected losses by an insurance company that can then use this value to price an insurance contract by adding a desired profit.

#### 4.4 Summary

For this study, first the BSM probability of bankruptcy was calculated for 100 companies randomly selected for different industries. 12 different risk pools of 5, 10, 25 and 50 companies were formed and tables with the probabilities that suppliers will go bankrupt in a year were calculated and used for the Monte Carlo insurance simulation. The simulation was able to show the expected risk reduc-

tion given a number of insurance policies sold and the expected losses for an insurance contract.

### Chapter 5. CONCLUSIONS

### 5.1 Research questions and answers

The answer to the first research question for the study "can the proposed supply chain risk management insurance model reduce the risk of bankruptcy of suppliers in a corporate setting?" is positive. Tables 3 and 4 show that model can be effective at reducing the targeted risk. Tables 3 and 4 also show that the insurance company would be able to benefit from a lower risk as the number of insurance policies sold increases. The answer to the second research question "Is the proposed model appropriate to calculate an insurance premium and risk that can used to implement the insurance model by insurance and financial institutions?" is also positive. Table 5 shows that average expected losses can be calculated from Monte Carlo simulations and these values can be used to price insurance premiums. Expected losses become more predictable by selling higher levels of insurance contracts (more than 50), these values can be used to price insurance contracts by adding a desired level of profit on top of the expected losses. As the risk of variability of losses decreases with the number of sold policies, insurance companies can have a high level of certainty that they will be able to profit from these contracts while the insured companies would be able to benefit by hedging the risk of bankruptcy of suppliers.

#### 5.2 Limitation of the results

The BSM used for the proposed model presents some limitations that can make challenging its implementation. The BSM model relies on financial public information that can be used to feed the model, this could be an important limitation given the fact that not all the suppliers are public companies that are traded in the stock market.

The suggested model assumes that companies in risk pool arrangements have uncorrelated losses; this is an important assumption that is required in order to reduce risk. However, in practice companies might have correlated losses; in particular, if they belong to the same industry that might be affected by similar events such as an economic crisis in a particular industry sector. The model can be affected by correlation of losses among companies that can be hard to measure.

Another important limitation of the proposed model in the complexity of the computations for the implementation of the model; this study was conducted with pooling arrangements of up to 50 companies but insurance companies might require larger sizes and this would require a large computer power that might make the model difficult to implement with average computer power.

#### 5.3 Future research

One of the main challenges of this research was the intensive computation required to produce the probability tables for a given risk pooling arrangement. Some of the calculations required several days to be produced and as the number of companies included in the risk pool increases, the time required to com-

pute these tables increase exponentially and the time required to compute large pools can be in the order of months. Future research should concentrate in the generation of equations that can make risk pooling calculations more efficient; these equations could use exponential regression analysis in order to fit the table in a simple equation that can be used to produce the probabilities with less intensive calculations. Insurance industry might not be able to use the proposed model unless simplified equations are produced that could make its implementation more efficient.

Future research should also explore the use of different bankruptcy models and measure the performance of these models against the BSM model. Although the BSM model proved to be robust for the proposed application, the literature in the field has several bankruptcy models that might be more suitable for the intended application in this research. For example, the model proposed by Flores-Lopez and Ramon-Jeronimo (2013), requires less data that might be hard to get for this type of analysis and explores the use of cooperative models and bootstrapping strategies for default prediction. The use of this model in combination with risk pooling and Monte Carlo simulations can be explored as a possible solution to the lack of availability of data for non public suppliers.

Future research should also focus on the development of losses models that can estimate the losses of bankruptcy per supplier. This research assumes that these losses are given but in practice these losses would need to be estimated by insurance companies. A losses model would be required for this task in the future.

### 5.4 Summary

The study clearly shows the usefulness of estimating the probability of bankruptcy of suppliers from available financial public information in order to create an insur-

ance contract that can hedge the risk of the supply chain. These insurance contracts can be managed by insurance carriers and sold to companies as supplier bankruptcy insurance. The research study applies financial and accounting theory to the supply chain risk management field and shows how this can be useful to create financial instruments for financial risk management hedging. As supply chains become more global and international economic events affect these chains, financial risk such as price, interest, default risks would need to be hedged and financial and accounting theory would become more relevant for this field. This research shows the potential benefit of financial and accounting theory to supply chains in the global context.
